HURRICANES OF 1954

WALTER R. DAVIS
Weather Bureau Office, Miami, Fla.

GENERAL SUMMARY

A feature of the 1954 hurricane season, as in 1953 [1] was the pronounced meridional movement of the four major hurricanes, which can be seen by inspection of figure 1. Again as in the 1953 season, the hurricanes recurved northward at low latitudes, and westward movement was at a minimum, with the exception of hurricane Hazel during the first 5 days of its existence. A quote from Norton's report [2] of 1952 is in order for the current season:

> The low hurricane activity was in keeping with past experience for summers with widespread drought over the eastern half of the United States. A study of drought summers during the past half century indicates that only about half as many hurricanes occur in them on the average as during normal or wet summers. This suggests that the general pressure distribution which causes widespread drought, reflects itself in lessened storm activity in the tropics as well.

Another unusual feature of this hurricane season was the absence of tropical storms in Florida, Georgia, and the east Gulf States and the passage of three hurricanes through the North Atlantic States and New England. Considering past experience which indicates normal expectancy of only 5 to 10 hurricanes per century in New England, 2 in 1 year is extraordinary.

The hurricane season of 1954 had about the normal number of storms, but was abnormal in other respects. All except 3 out of a total of 8 storms were of hurricane intensity, Barbara and Gilda being of less than hurricane intensity. The intensity of Florence was not definitely determined. No storm was charted from the eastern Atlantic; in fact, all were charted west of longitude 65° W., with the exception of Hazel which had its origin between 55° and 65° W. Three major hurricanes, Carol, Edna, and Dolly originated only a short distance east of the Bahama Islands, while Hazel, the fourth major hurricane, built up in the eastern Caribbean. Of these four, Carol, Edna, and Hazel played havoc with the Atlantic States from the Carolinas northward during the 7-week period from August 30 to October 15. Dolly remained at sea, inflicting no coastal damage.

Hurricane Carol brushed the North Carolina coast and moved rapidly northward and inland into the New England States, causing about 60 casualties and a loss in excess of $460 million to property, crops, etc., in the North Atlantic States. No deaths were reported from North Carolina, and damage to that area was $227,500. Hurricane Edna came close on the heels of Carol, and all the North Atlantic area was eager to take precautions for the protection of life and property. Edna accounted for 20 casualties, mostly drownings, and over $42 million in damage, mainly from the Long Island area northward across New England. Precautionary measures were well in order for the populace when hurricane Hazel came along a month later. Hazel resulted in 20 deaths on the Carolina beaches and about $163 million in damage to the Carolina beaches and the interior of North Carolina. The death toll for the area along the hurricane's path north of the Carolinas into the Canadian provinces of Quebec and Ontario was about 149 with 78 of the total in Canada. Damage estimates for this area total over $148 million plus additional damage particularly in Virginia and New York for which figures are not available.

Total casualties from hurricanes Alice, Carol, Edna, Florence, and Hazel on the North American mainland were approximately 311, 43 of which were in Mexico and 78 in Canada. Total damage was likely in excess of $1 billion. A total of 104 advisories were issued and numerous bulletins for press and radio, hoist orders, special orders, etc., by the forecast offices concerned. The service, by allowing time for protective measures, reduced potential casualties and damage.

INDIVIDUAL HURRICANES

Alice, June 24–26.—A tropical storm developed rapidly in the west Gulf of Mexico on the 24th of June and by early on the 25th was of hurricane force. It moved inland south of Brownsville, Tex., early on the morning of the 25th. A fishing camp along the Mexican coast, about 100 miles south of Brownsville, estimated a maximum wind of 70 to 80 m. p. h. The storm moved up the Rio Grande Valley and passed over Laredo, Tex., late on the 25th. Apparently very little damage was caused by the winds and tides associated with the storm and only one death occurred in the Brownsville area. The major damage and casualties resulted from the floods on the Pecos and lower Rio Grande, caused by the attendant heavy rains. Seventeen deaths were reported in Texas and an estimated 38 in Mexico. There was considerable damage to crops, principally cotton. Dollar damage is not available.

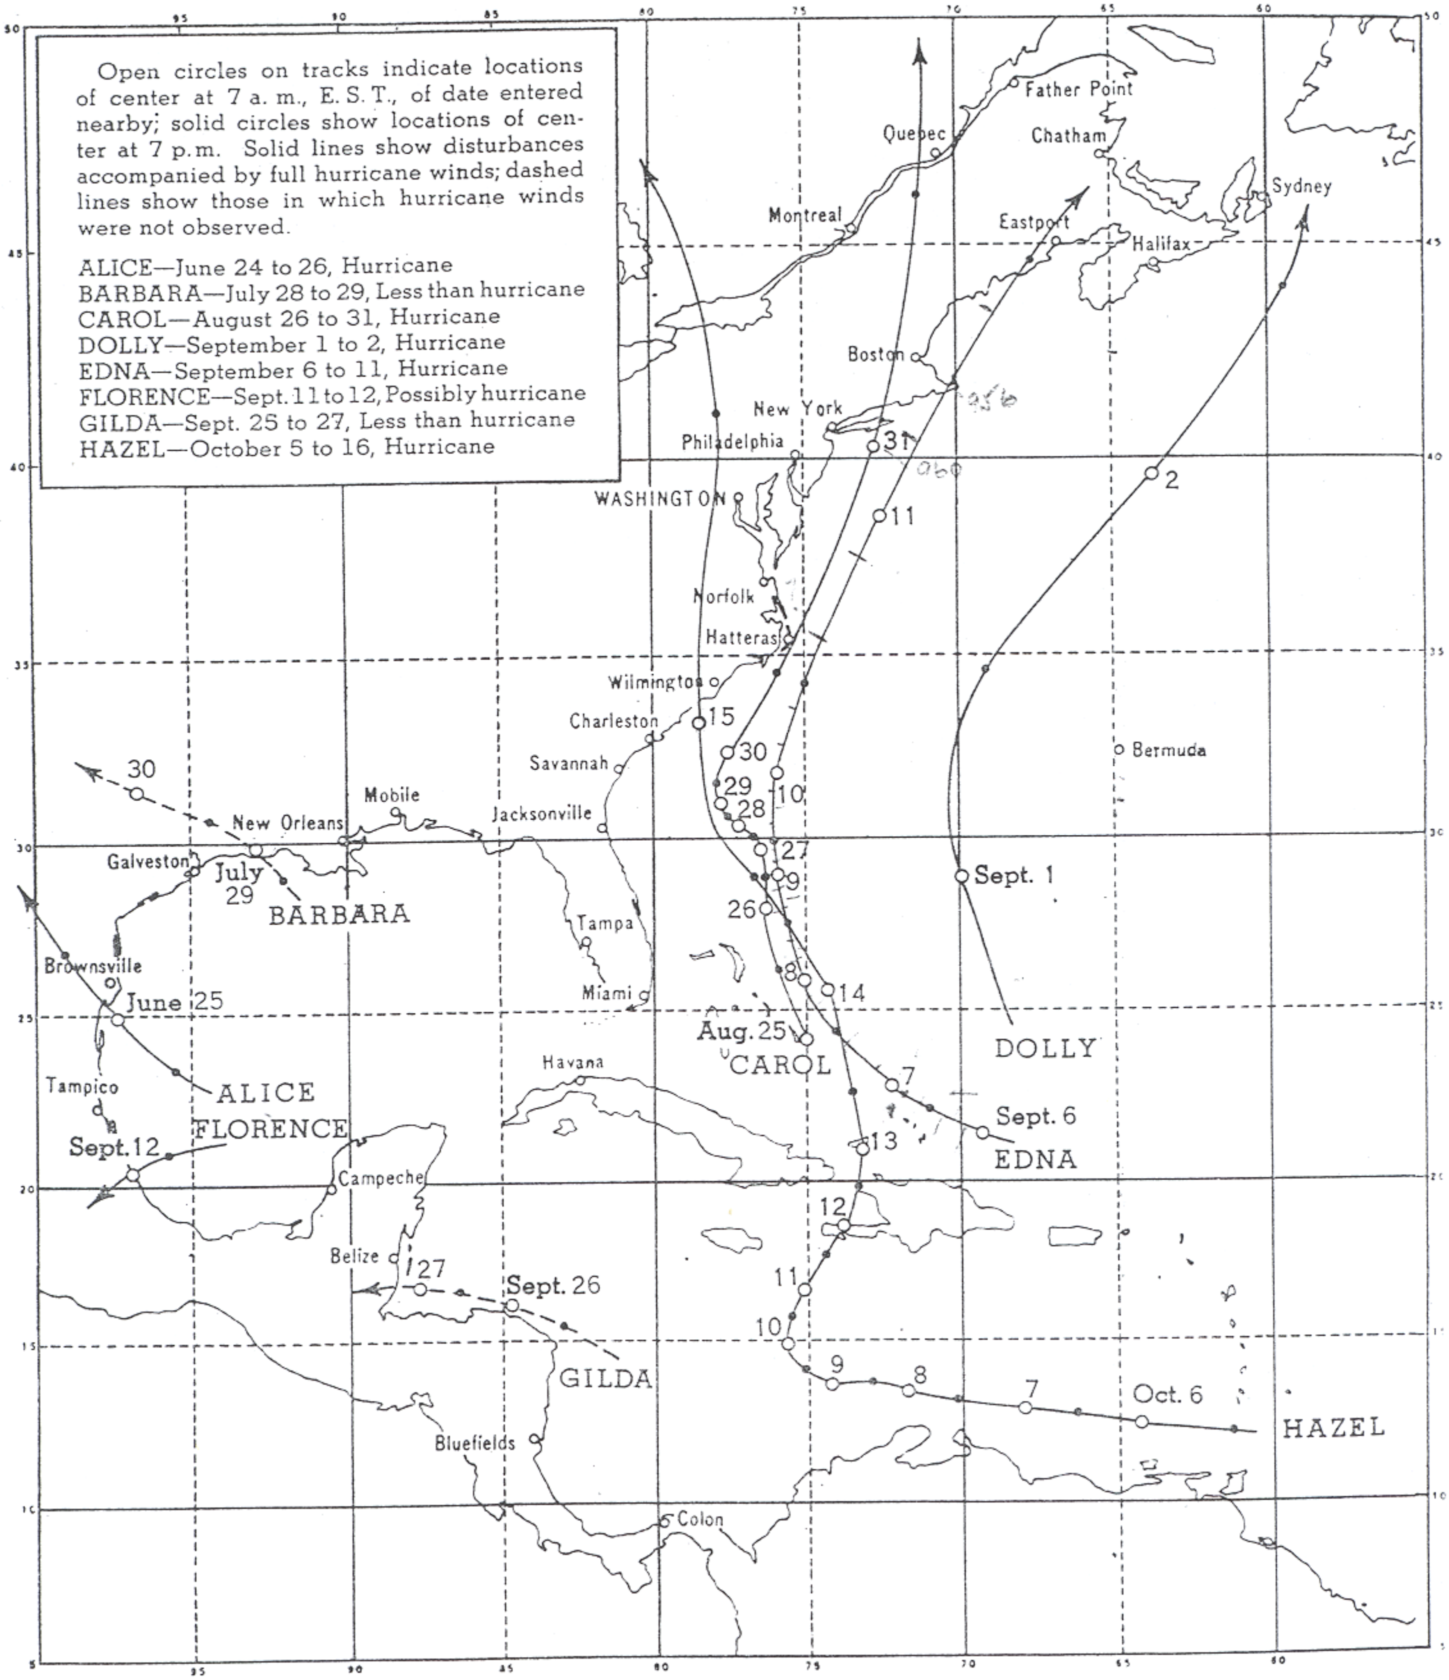

FIGURE 1.—Tracks of hurricanes of 1954.

Barbara, July 28–29.—This storm formed in the north Gulf of Mexico off the Louisiana coast on July 28 and moved inland in the Vermilion Bay area early on the morning of the 29th. Highest wind reported was 60 m. p. h. by the *Henry M. Dawes* on the afternoon of the 28th. Some damage to crops, such as rice and corn, was reported from the heavy rains, but the general opinion was that the rains associated with the storm were far more beneficial than damaging. Wind damage was negligible.

Carol, August 26–31.—Hurricane Carol formed from a weak easterly wave during the night of August 26 and the forenoon of the 27th near the northeastern Bahama Islands. After forming it moved northward to a position near 30° N., 76° W., where it came to a near standstill, but during the ensuing 3 days it drifted very slowly to about 32.5° N., 77.5° W. on the 30th. It then began an accelerating north-northeast movement and passed very near Cape Hatteras about 2100 or 2200 EST on the 30th. Highest winds, estimated by reconnaissance aircraft, varied from 75 to 125 m. p. h. When the hurricane passed the North Carolina Capes, with all reporting stations on the weaker side, the west, highest wind speeds on land were gusts of 55 m. p. h. at Wilmington, 65 m. p. h. at Cherry Point, and 90 to 100 m. p. h. at Cape Hatteras. Damage in North Carolina was estimated at $227,500 with no deaths.

By the morning of the 31st Carol was just south of Long Island and moving rapidly north-northeastward. It crashed across the New England States diminishing as it swept into Canada. Highest winds were at Block Island, R. I., where 130 m. p. h. was measured in gusts. The storm left 60 dead and over $460 million damage to property and crops in the North Atlantic States. About one-third of Providence, R. I., was under 8–10 feet of water for several hours and many shore communities were demolished.

A discussion of hurricane Carol in relation to the planetary wave pattern has been given by Winston [3].

Dolly, September 1–2.—This small hurricane formed in an easterly wave near 26° N., 69° W., during the night of August 31–September 1, and by early morning of the 1st was near 29° N., 70° W. It moved very rapidly northward and northeastward and by afternoon of the 2d was east of Nova Scotia, reduced in force, and rapidly becoming extra-tropical. Strongest winds estimated by aircraft were around 100–115 m. p. h. on the afternoon of the 1st. This hurricane remained at sea and no damage was reported.

Edna, September 6–11.—Hurricane Edna formed in an easterly wave on the afternoon of September 6 near 22° N., 70° W., and increased to hurricane intensity during the night. During the 7th and 8th it swept the outer Bahama Islands as it moved on a broad curving path northward. The center passed very close to San Salvador Island, Bahamas, late on the 7th where winds were up to hurricane force in gusts, but no appreciable damage resulted. High seas and gale winds were experienced on the outer fringe islands northward to Great Abaco. During the 9th and 10th, the storm moved northward very near the 76th meridian and gradually turned to the north-northeast closely paralleling Carol's path 11 days earlier. It passed just east of Cape Hatteras early in the night of the 10th and winds of about 75 m. p. h. were felt on the North Carolina Capes from Cape Lookout to Manteo. Thereafter, it moved rapidly northeastward and passed about over Cape Cod on the 11th, and thence moved into eastern Maine, Nova Scotia, and New Brunswick that night where it caused great damage and some loss of life. There was no loss of life in North Carolina where damage was minor. Damage in New England was estimated at over $40 million and there were 20 casualties. Strongest winds were estimated by aircraft at about 115 to 120 m. p. h. The highest wind speed over land (95 m. p. h.) was measured at Brookhaven National Labratory, Long Island.

The meteorological conditions associated with the formation and movement of hurricane Edna have been analyzed by Malkin and Holzworth [4].

Florence, September 11–12.—This storm formed in the southwestern Gulf of Mexico and moved into Mexico between Tuxpan and Nautla on the morning of September 12. The highest wind reported by reconnaissance aircraft was about 65 m. p. h. The press reported 5 dead and more than $1,500,000 damage around the oil center of Poza Rica, mostly to the banana crop. The storm was possibly of hurricane force as it hit the coast.

Gilda, September 25–27.—Small tropical storm Gilda formed in the Caribbean Sea east of Cape Gracias, Nicaragua on September 25 and moved westward along the north coast of Honduras and into British Honduras near Stann Creek, about 60 miles south of Belize, around 1530 EST of the 27th. The storm was less than hurricane force throughout its life, with highest winds of 60 to 70 m. p. h. in squalls. Damage was slight to buildings and no casualties resulted directly from the storm. Rainfall was very heavy in northern Honduras, resulting in disastrous floods, especially around San Pedro Sula, La Lima, and the adjacent valley areas. Press reports indicated 29 dead and thousands homeless and marooned in the flooded area, and extensive damage to property and crops.

Hazel, October 5–16.—This hurricane developed in an easterly wave at latitude 12° N., longitude 61.2° W., on October 5 at which time highest winds were estimated about 100 m. p. h. The hurricane passed near or slightly north of the island of Grenada in the Windward Islands and into the Caribbean Sea during the evening of the 5th. It continued on a west to west-northwest course until the night of the 9th–10th when it slowed in forward speed and curved northward. During this period, the hurricane slowly gained in size and intensity; highest winds were 115 m. p. h. on the 7th and 125 m. p. h. on the 8th, as estimated by reconnaissance aircraft. On the latter date, the Navy reconnaissance plane encountered severe turbulence and one member of the crew was severely injured, requiring hospitalization, and another sustained minor injuries.

The hurricane moved on a north-northeast course from the night of the 10th–11th until it passed through the Windward Channel and into the southeast Bahamas on the morning of the 13th. It changed course to north then to north-northwest on the 13th, continuing on that course until it passed inland on the North Carolina coast about 0915 EST of the 15th.

Considerable damage and loss of life resulted in Haiti, especially on the southwest peninsula. This area is very mountainous, with peaks up to almost 8,000 feet in the western portion. High winds and seas and torrential rains resulting in floods and landslides accounted for the loss of life, estimated between 400 and 1,000, including 200 or more buried in landslides. The dollar estimate of damage is not available.

After passing through the Windward Channel, the hurricane moved northward over the island of Great Inagua, Bahamas, between Mayaguana and Acklin Islands and passed a short distance east of the remainder of the Bahamas. Six lives were lost, out of a total of 15 aboard, when a sailboat capsized that was trying to take shelter at Inagua on a trip from Turks Island. Damage to property and salt mining was minor at Inagua, and only minor damage resulted elsewhere in the Bahamas.

At Inagua a minimum pressure of 29.34 inches was recorded and a maximum wind of 40 m. p. h. The center passed a short distance to the east of the observing station; however, the comparatively light wind indicated that the hurricane had become distorted and the strong surface winds apparently deflected aloft while passing through the mountainous terrain bordering the Windward Channel. The exposure of wind instruments at Inagua is excellent, with no obstructions to free wind flow.

Storm warnings were hoisted at 1100 EST on the 14th from Charleston, S. C., northward on the Virginia Capes, and the remainder of the coast northward to New England was placed on the alert by Washington and Boston Weather Bureau offices. Warnings were adjusted slightly before the center moved inland; however, the affected area from Charleston northward had 24 hours warning, and of course, had been watching the movement of Hazel for several days prior to the 15th.

During the 14th and 15th, and until the hurricane passed inland, the highest winds were estimated in all warning messages in excess of 100 m. p. h. Wilmington, N. C., reported a top gust of 98 m. p. h. and the fastest mile was 82 m. p. h. Minimum pressure there was 28.68 inches. Myrtle Beach, S. C., reported top gusts of 106 m. p. h. and lowest pressure of 28.47 inches. (This was the lowest pressure reported on land although 27.70 inches was reported by a fishing boat at Tilgham Point while in the eye of the storm at 10:30 a. m. EST.) Wind estimates from several points between Myrtle Beach and Cape Fear varied from 130 to 150 m. p. h. The devastation along the North and South Carolina beaches was staggering. Every pier in a distance of 170 miles of coastline was demolished and whole lines of beach homes literally disappeared. In some places the tide was over 17 feet higher than mean low water.

Rainfall was heavy along and to the west of the storm track in North Carolina. Record 24-hour amounts ranged from 6.5 inches at Burlington, High Point, and Lexington up to 9.72 inches at Carthage, located in the sandhills section of the southern Piedmont. One U. S. Geological Survey station at Robbins, several miles north of Carthage, reported 11.25 inches. Rainfall in the eastern half of the storm was comparatively light, several stations reporting less than an inch.

Total casualties in the Carolinas were 20, most of which were drownings. Damage to the Carolinas is estimated at around $163 million with $36 million from the North Carolina beach area, $25 million from the South Carolina beach area, and the remainder from crop and property losses in the interior.

In the 12 hours after Hazel struck the Carolina coast it traveled with extreme speed on a north-northwest track, sometimes at 60 m. p. h. It passed through the western suburbs of Washington, D. C., and spun across Pennsylvania and New York into Ontario maintaining its intensity all the way. Peak wind speeds of 90 m. p. h. or over were reached near and east of the center from the Carolinas through New York and a pressure 28.75 inches was measured at Richmond, Va. Rainfall was heavy on the west side of the storm—over 9 inches in western Virginia and over 10 inches locally in the Appalachians. Floods were destructive in western Pennsylvania, and in Toronto, Ontario, and vicinity floods took 78 lives.

A discussion of hurricane Hazel in relation to the large-scale circulation has been given by Krueger [5] and a detailed State-by-State account of path and damage is presented by Seamon [6].

ADDENDUM TO "HURRICANES OF 1954"

(*Monthly Weather Review,* vol. 82, No. 12, Dec. 1954, pp. 370–373)

To complete the hurricane record of 1954, the hurricane in mid-Atlantic during the period of September 30–October 5, 1954, should be included. It was not given a name at the time, because it was obvious that it would not move any great distance toward the west. As an un-named hurricane, it was not included in the 1954 list. However, it is now believed that this hurricane should be included in the 1954 tabulation. The track is given in figure 1.—*Gordon E. Dunn, Walter R. Davis, and Paul L. Moore, WBO, Miami, Fla.*

HURRICANE EDNA, 1954

WILLIAM MALKIN AND GEORGE C. HOLZWORTH
WBAN Analysis Center, U. S. Weather Bureau, Washington, D. C.

INTRODUCTION

Hurricane Edna was the second tropical storm of 1954 to penetrate the east coast of the United States, the center reaching into New England on September 11, some 11 days after Hurricane Carol. While total loss of life and damage to property for Edna were less than for Carol, the tracks were similar. A reexamination of some of the meteorological conditions associated with the formation and movement of Edna may reasonably be expected to have elements in common with other storms of similar life history. Coincidentally, while this article was being written, Hurricane Hazel, about one month after Edna, moved inland across the South Carolina coast on October 15, and accelerated northward, maintaining exceptional intensity for a tropical storm moving over land. Although Edna was the least spectacular of the three hurricanes, its occurrence in September calls for it to receive most of the authors' attention as a contribution to the review of September's weather. Only incidental references are made to Carol and Hazel.

THE FORMATION OF EDNA

The first surface indication of an apparently closed circulation that subsequently evolved into Hurricane Edna was noted the night of September 5, in the extreme southwestern Atlantic between Puerto Rico and the Bahama Islands. Some forewarning of the possible formation of a tropical storm was given by a 2100 GMT, September 5 ship report from a position near 22.5° N., 67.7° W. This report from *The Bulk Oil* stated that she was encountering very heavy squalls, winds to 50 m. p. h., with gusts to 70 m. p. h., and rapidly falling barometer.

As is usual when storms form along the West Indies, Edna developed within an extensive easterly wave that had recently moved into the region. Another indication of possible cyclogenesis was the intense rainfall experienced over Puerto Rico with the passage of the easterly wave. Widespread rain had been observed at the regularly reporting stations; however, it was not until the receipt of a bulletin from San Juan on September 7, after the formation of Edna was an established fact, that the extent of this rainfall was realized. The bulletin from San Juan stated that intense rains had flooded the entire southern and western coastal sections of the Island, some stations reporting more than 4 inches of rain in a 24-hour period, while other sections had more than 10 inches during a 2-day period. With respect to convective rain, at any rate, the easterly wave within which Edna formed, showed exceptional activity in the day or so prior to formation of the storm.

Several ship reports on the surface chart for 0030 GMT, September 6, gave more positive indications that a tropical storm was developing in the region just northeast of Santo Domingo. At this time the center was located at 21.6° N., 68.5° W. While the winds had not yet reached hurricane force, the first advisories at that time predicted intensification.

THE TRACK OF EDNA

Prior to 1830 GMT, September 6, ship reports in the immediate vicinity of the storm were sparse, and therefore the positions shown for the storm track (fig. 1), in this time interval, should be viewed with some skepticism. Likewise, the loops shown in the track, while based on a careful consideration of the few reports available at the time, are not certain features, except with respect to very slow movement of the center at the respective positions. The final track, as pictured in figure 1, takes into consideration all available ship and island reports, aircraft reconnaissance, land-based radar reports, and Weather Bureau bulletins.

In the period prior to recurvature, 0030 GMT, September 6 to about 1830 GMT, September 9 inclusive, the track appears to have a rather uniform oscillation of small amplitude with period of about 26 hours. The regularity of these oscillations prior to recurvature compares quite favorably with those pictured by Yeh [1], who has developed the following interesting yet simple formula relating the period of oscillation with several variables pertaining to the low level structure of a hurricane:

$$T=\frac{4\pi R^2}{2v_0r_0-fR^2}$$

where T is the period, v_0 is the maximum wind speed, r_0 is the distance from the center to v_0, f is the Coriolis parameter and R is the radius over which air is assumed to move

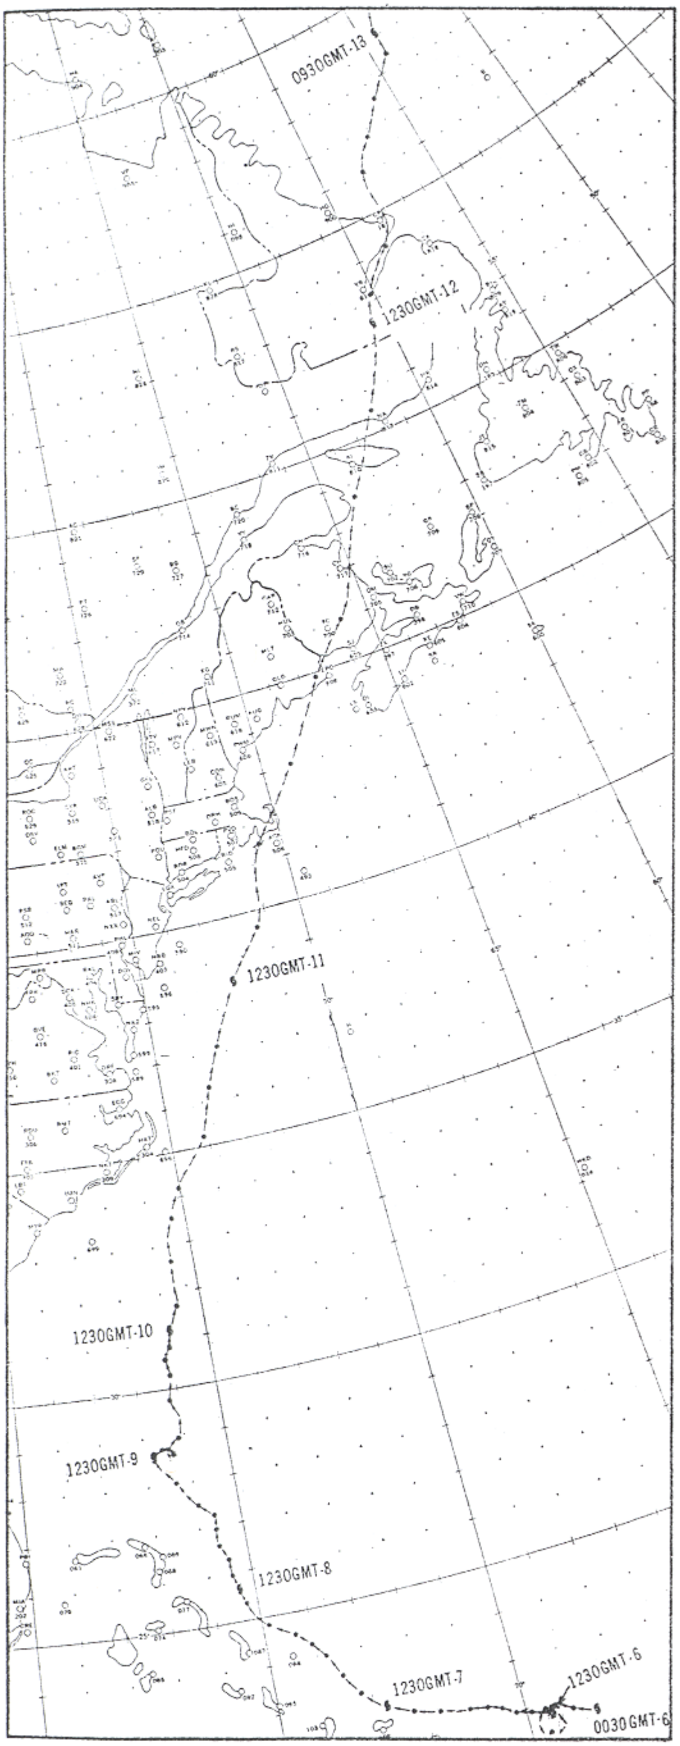

FIGURE 1.—The track of Edna, shown in 3-hourly intervals.

with the vortex. As the 26-hour period of oscillation in the 3-day interval was judged to be accurate to within 10, and possibly 5 percent, T, the period, was used as one of the "knowns" in making a trial substitution into Yeh's equation. For the maximum wind, the value of 120 m. p. h., from the *Fairland* in the forward semicircle, agreed quite well with the report of maximum wind slightly over 100 knots received from reconnaissance. Also, along this portion of the track, a reasonably accurate estimate for the diameter of the eye, obtained by averaging the values from a number of reconnaissance reports, was 25 miles. With the eye itself having a radius of just over 10 miles, a compromise between several reports on the extent of the region with maximum winds indicated that a total distance of 25 miles out from the center was a reasonable estimate for the radius distance to the maximum winds. Substitution into Yeh's formula, using 0.6×10^{-4} sec.$^{-1}$ for the Coriolis parameter, gives about 95 miles for the value of R, which result may be looked upon as the radius of the storm. This value was considered to be of the right order of magnitude. However, in working further with the equation, it soon became apparent, as recognized by Yeh [1], that even for a small storm, much more detailed observational data than now currently available would be required to test or apply the relationships involved. In attempting to solve for the period, several trial computations have indicated that only small changes in the other variables, within present limits of observation, lead to large differences in the resulting period. The equation is very sensitive to v_0, r_0, and R, such that there is little hope, at present, of applying the formula with expectations of specific and consistent results.

Soon after 1230 GMT, September 9 and until about 2130 GMT of the same day, aircraft reconnaissance radar reports became confusing. For example, the center was at times reported to be stationary, followed by a report indicating a sudden displacement southeastward; still a later report again mentioned stationary, and subsequently another indicated a sudden northeastward movement. A careful post-analysis indicates that some of the reports were inconsistent. It has been shown that errors in interpretation of radar echoes have occurred [2], and some may be due to the fact that the beam picks up the nearest squall band which may blot out possible echoes from behind the band. Occasionally, false eyes have been encountered [3], as proven by instances when the mistakes were subsequently discovered by the reconnaissance aircraft while in flight, and corrected messages sent. This happened at least twice during the reconnaissance of Edna.

Some of the difficulties and disappointments in accurately locating the eye of a storm may be caused by the eye often being in a state of flux, and, in particular, frequently possessing an isolated and centrally located cloud [4] of variable size, such that, to an aircraft in flight, the central cloud bank may visually blend in with the true outer cloud walls of the eye. It is therefore apparent that a storm track such as ours of Edna, does not begin to re-

veal the smaller scale, but nonetheless significant, variations in eye structure and relative position.

While the report by Gutenberg [5] concerning the usefulness of microseisms in tracking hurricanes is encouraging, the authors have not given attention to this aspect of Edna, based on information from Kammer [6] and Dinger [7], that the microseismic technique for the tracking of tropical storms is no longer looked upon with as much enthusiasm as several years ago. Among the reasons given for this change of opinion is doubt that the signal is generated in the immediate vicinity of the hurricane; it is thought rather that the energy is introduced into the earth by some type of wave action at variable and considerable distances from the storm.

LAND-BASED RADAR REPORTS ALONG EDNA'S TRACK

Radar reports from the vicinity of Norfolk, Va., and records of synoptic reports from Norfolk itself, describe vividly the sequence of weather as Edna approached these stations from the south-southwest and passed about 120 miles to the east on a track to the north-northeast. Figure 2 is a composite, which includes the detailed track of Edna as determined by radar from this vicinity. The barograph trace and surface observations in the figure are from Norfolk.

The radar reports show that at 0150 EST, September 11, the eye of Edna was closest to Norfolk. The barograph trace shows that although pressure began to level off at about that time, it actually continued to fall until about 0230 EST. A degree of eccentricity in the associated structure of the storm is therefore indicated. The strongest sustained winds at Norfolk were 30 m. p. h., with gusts to 50 m. p. h. It was noted that with the passage of Edna to the northeast and the shift of surface wind from northeasterly to northwesterly, the temperature remained practically constant, while the dew point dropped perceptibly.

Before the eye of Edna approached to within radar range of the Norfolk vicinity, spiral rainbands were observed and recorded every half hour from 1910 GMT, September 10 to 0110 GMT, September 11. Three successive plots of these rainbands are reproduced in figure 3 showing how the rainbands changed in shape and orientation with time. It was interesting to find that the perpendicular bisectors of the chords across each of the band end points in every instance crossed the track in advance of the eye. This crossing of the track of the storm, by the perpendicular bisector, ahead of the eye, is geometrically consistent with bands located in the northwest quadrant that are spiralling in toward the center.

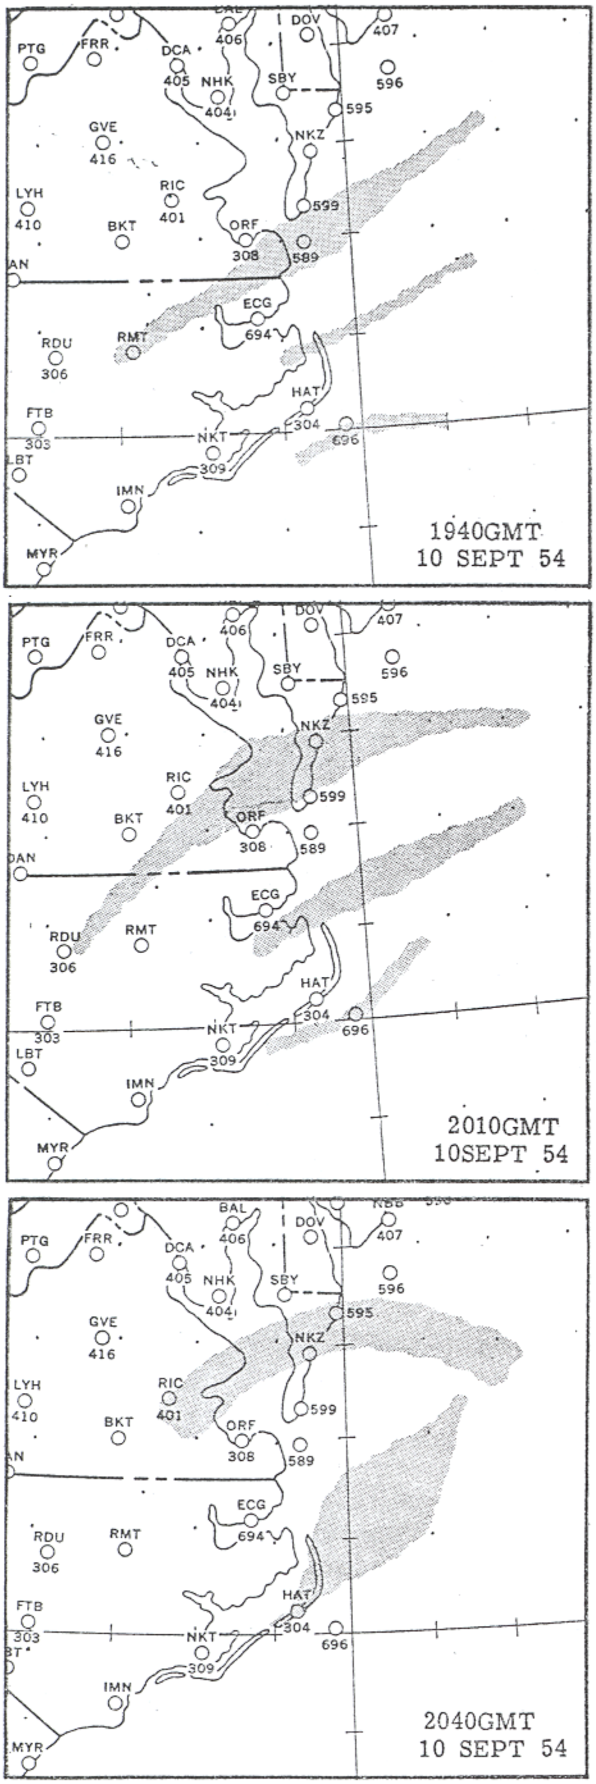

FIGURE 3.—Plot of radar echoes as observed from the Norfolk, Va. area, showing the rapidity with which spiral bands change shape and size.

DEVELOPMENTAL STAGES

The storm was in the formative stage (Riehl [2]) by 1830 GMT September 6, (fig. 4), judging from a fairly dense coverage of ship and island reports. At that time, the strongest winds, while still below full hurricane force, were concentrated north and east of the deepening center. Lowest surface pressure was about 1,000 mb. In the following 18 hours, Edna continued to move slowly toward the west-northwest.

At 1830 GMT, September 7 the storm veered slightly toward the northwest (fig. 1). Edna then appeared to be in the immature stage (fig. 5), characterized by rapidly falling central pressure, full hurricane-force winds, as reported by reconnaissance, in an apparently tight ring

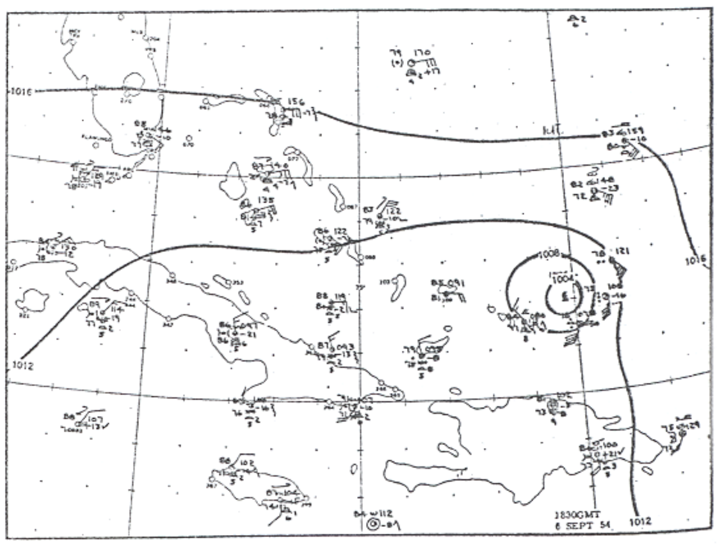

FIGURE 4.—Surface weather chart for 1830 GMT. September 6, 1954. The usual plotting model was used, except visibilities were omitted. At this time Edna was considered to be in the formative stage.

around the center, with squalls and spiral cloud bands in the process of becoming organized. Reconnaissance reports of minimum pressure gave 1,001 mb. at 1430 GMT, September 7, and 992 mb., 5½ hours later. As yet, the storm covered only a relatively small area. By mid-day September 7, aircraft reconnaissance was regularly sending radar fixes of the eye, along with other pertinent information. As all ships in the area were then attempting to give wide berth to Edna,[1] these radar fixes were invaluable for tracking the storm and estimating its development. Some of the remarks received from reconnaissance aircraft, descriptive of conditions near the eye on September 8, while the storm was in this immature but developing stage, are as follows:

0330 GMT. Altitude 8,000 feet. Eye position is center of 20 mile diameter hole [in radar echo] to sea. Weather band pattern on radar very confused. Positions in previous two reports based on horseshoe shape at end of weather band and believed in error by 25 miles too far north.

0430 GMT. Altitude 8,000 feet. Eye is circular hole [in radar echo] to sea, 20 miles diameter, fix believed accurate. Weather bands intensified slightly past hour but do not clearly define eye. Heaviest weather northern semicircle.

0530 GMT. Eye now fairly well defined by weather and sea. Squall bands extend 80 to 100 miles northern semicircle and 70 miles southern semicircle from eye.

0630 GMT. Altitude 8,000 feet. Definite increase in size and number of weather bands, now well developed spiral, equally [developed] in northeast quadrant during past hour. Eye well defined, circular, 20 miles diameter.

0730 GMT. Altitude 8,000 feet. Weather increased slightly in extent and intensity all quadrants, especially northwest quadrant near eye during past hour. Prominent spiral band now extends 140 miles north of eye. Eye will defined on radar.

0900 GMT. Altitude 8,000 feet. Now able to pick up eye at 90 miles [from eye]. Previously had to run in to within 30 to 40 miles [of eye]. Squalls now extend 100 miles from eye south semicircle and 150 miles north semicircle. Radar sea return [echo] indicates surface winds of about 80 to 90 knots near eye in northern semicircle. Squalls still intensifying all quadrants. Departing storm area.

1000 GMT. Radar indicates Edna developing rapidly. Lost eye at 150 miles [from eye].

A portion from one of the surface maps during the interval when Edna was in the mature stage, is shown in figure 6. From all indications, the central pressure had stopped falling, while simultaneously, the circulation had been expanding and the radius of hurricane-force winds had increased. Scarcity of data precludes positive verification that the storm lost symmetry and that the area of bad weather had extended itself farther to the right of the motion than to the left, both of the above features being typical of the mature stage.

Edna had little effect on continental United States until several hours after 1830 GMT, September 9. It was then that the storm accelerated almost directly northward in

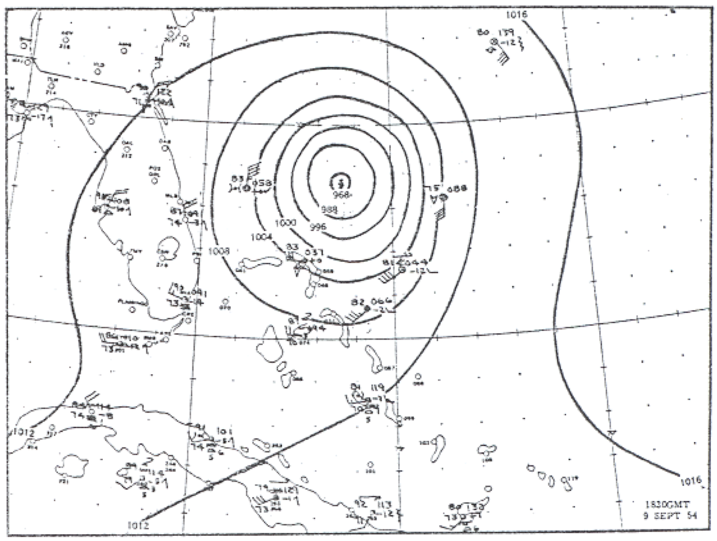

Figure 6.—Surface weather chart for 1830 GMT, September 9, 1954. At this time Edna was believed to be in the mature stage. To avoid crowding, several isobars have been omitted.

[1] One ship, the *Fairland*, was caught in the eye and was seen from the reconnaissance aircraft flying in the eye [4].

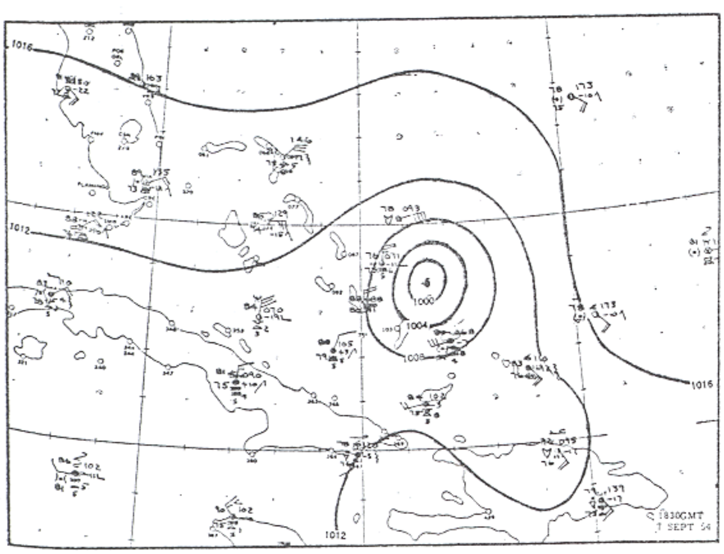

Figure 5.—Surface weather chart for 1830 GMT, September 7, 1954. At this time Edna was believed to be in the immature stage.

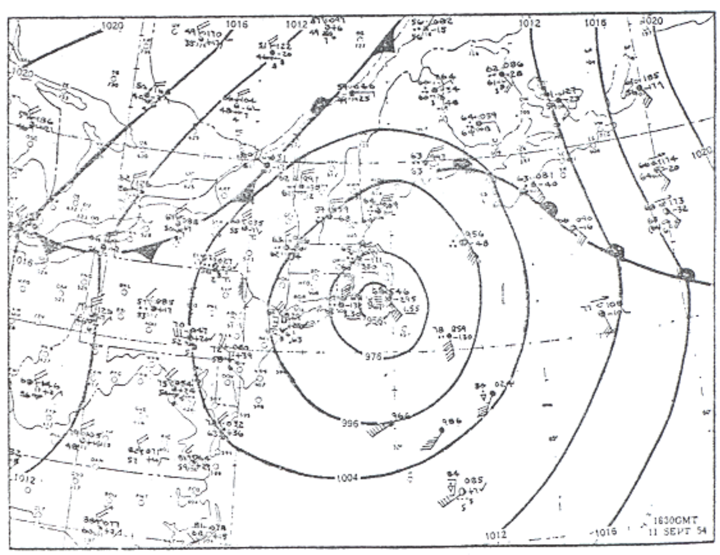

Figure 7.—Surface weather chart for 1830 GMT, September 11, 1954.

the general direction of Cape Hatteras. Stations on the southeastern seaboard began to report rapidly increasing cloudiness. A weak quasi-stationary surface front extended eastward along the southern Tennessee border to South Carolina and thence northeastward into the Atlantic, but there was little weather associated with this diffuse front. As the hurricane progressed northward, the onshore winds increased in speed and the cloudiness spread inland from the Carolinas through Pennsylvania. The Appalachian Mountains and the quasi-stationary front with its cooler air to the north, served as a barrier, promoting upslope motion, thereby increasing the cloud cover. Over New England, the flow was also onshore due to the presence of a ridge of high pressure to the northeast, which accounted for the cloudiness that already existed there. By 0630 GMT, September 10, all States on the Atlantic coast north of the Carolinas were covered by a continuous cloud deck.

Meanwhile, an occluded Low, with its associated precipitation pattern, was centered over Lake Michigan and moving eastward. At this time also, rain from the hurricane began to fall along the coast of the Carolinas. At 2130 GMT, September 10, Edna was located just south of Cape Hatteras and the rain area had spread inland and northward to New Jersey. The weak quasi-stationary front extending eastward across the coast and into the Atlantic was torn apart as the hurricane circulation moved northward. By 0630 GMT of the 11th, Edna was about 115 miles northeast of Cape Hatteras and moving toward New England at a comparatively fast speed. The occluded Low moving east from the Great Lakes was then filling. As Edna moved toward New England, stations along and near the coast reported rapid clearing and cessation of rain, soon after the storm center passed to the north of their respective latitudes. Meanwhile, in the New England area, the rains had intensified to a steady downpour and the winds had increased to gale force with frequent strong gusts. At 0030 GMT, September 12, Edna was centered just a few miles west of Eastport, Maine, having passed directly over Cape Cod. Soon thereafter, communications in the area were disrupted, and it was difficult to accurately determine the position of the storm. Continued rapid northeastward movement was subsequently verified.

Definite criteria are not available to fix the time at which Edna became extratropical or entered into the decaying stage. As the storm moved away from New England, it followed the trough along a cold front into a Low to the north (see fig. 7) a sequence of events which is known to forecasters to be conducive to only slow decrease in intensity. Other symptoms of the decaying stage that are considered to be typical include decrease in size after recurvature and upon entering the westerlies, and loss of tropical characteristics while becoming extratropical. After moving up through Canada, Edna, then an extratropical storm, passed into the Atlantic on a track toward the east.

ASPECTS OF THE VERTICAL STRUCTURE

Figure 8 is a space cross section through the eye of Edna, showing constant pressure and thickness profiles. The dropsonde in the eye was released at 700 mb., and the sounding extrapolated up to 125 mb., taking into consideration mean eye values shown by Riehl [2]. This extrapolated portion of the sounding may be somewhat too cold in the region just above 700 mb. Over the eye, the tropopause was considered to lie above 125 mb. At the time of the cross section, Edna was centered just southwest of Nantucket and moving toward an extratropical Low located to the north in Canada. While Edna was still of tropical structure, she was now in the vicinity of an upper cold Low, and subject to modifications from this source as well as from the extratropical air now enveloping the area at the surface.

If thicknesses are chosen for constant pressure surfaces such that these constant pressures are always in the same ratio, then from hydrostatic considerations, equal thicknesses will have the same mean virtual temperature. The constant pressure surfaces in figure 8 were selected with this relationship in mind. The height and thickness profiles illustrate that the low central pressure (946 mb.) was not counterbalanced by the warm core, even to 125 mb., there being some trace of gradient cyclonic flow even at this level. At Cape Hatteras, N. C., the tropopause was at 93 mb., and at Caribou, Maine, it was located at 145 mb. Large differences in temperature of the lower stratosphere were associated with the change in slope of the 62.5-mb surface. For while the 125-mb. level was 440 feet lower at Caribou than at Cape Hatteras, the 62.5-mb. level was 100 feet higher at Caribou. So the layer 125 mb. to 62.5 mb. was 540 feet thicker at Caribou than at Cape Hatteras. Since for thicknesses whose constant pressure surfaces are in the ratio of 2:1, a difference of 200 feet equals a difference in temperature of 3° C., the layer 125 mb. to 62.5 mb. was about 8.1° C. warmer at Caribou than at Cape Hatteras. Data were not available near the eye at these high levels, and a similar thickness comparison there is consequently not given.

Of the several thicknesses, the 500 mb. to 250 mb. stratum showed the greatest thickness variation between the eye and the two stations at the extremities of the cross section. From figure 8, the variation in thickness for this stratum between Cape Hatteras and the eye was 740 feet (about 11.0° C.), while the variation in thickness of the stratum between the eye and Caribou was 900 feet (about 13.4° C.). Some of this 900-foot variation was related to the cold Low situated to the north of Caribou.

It can be seen from figure 8 that the strongest gradients in the constant pressure profiles occurred near the eye of the hurricane, where the strongest winds were observed. The gradient decreased with altitude, and the winds likewise. Thus, the thermal winds around the eye were anticyclonic, and this agrees with the structure of a warm core Low.

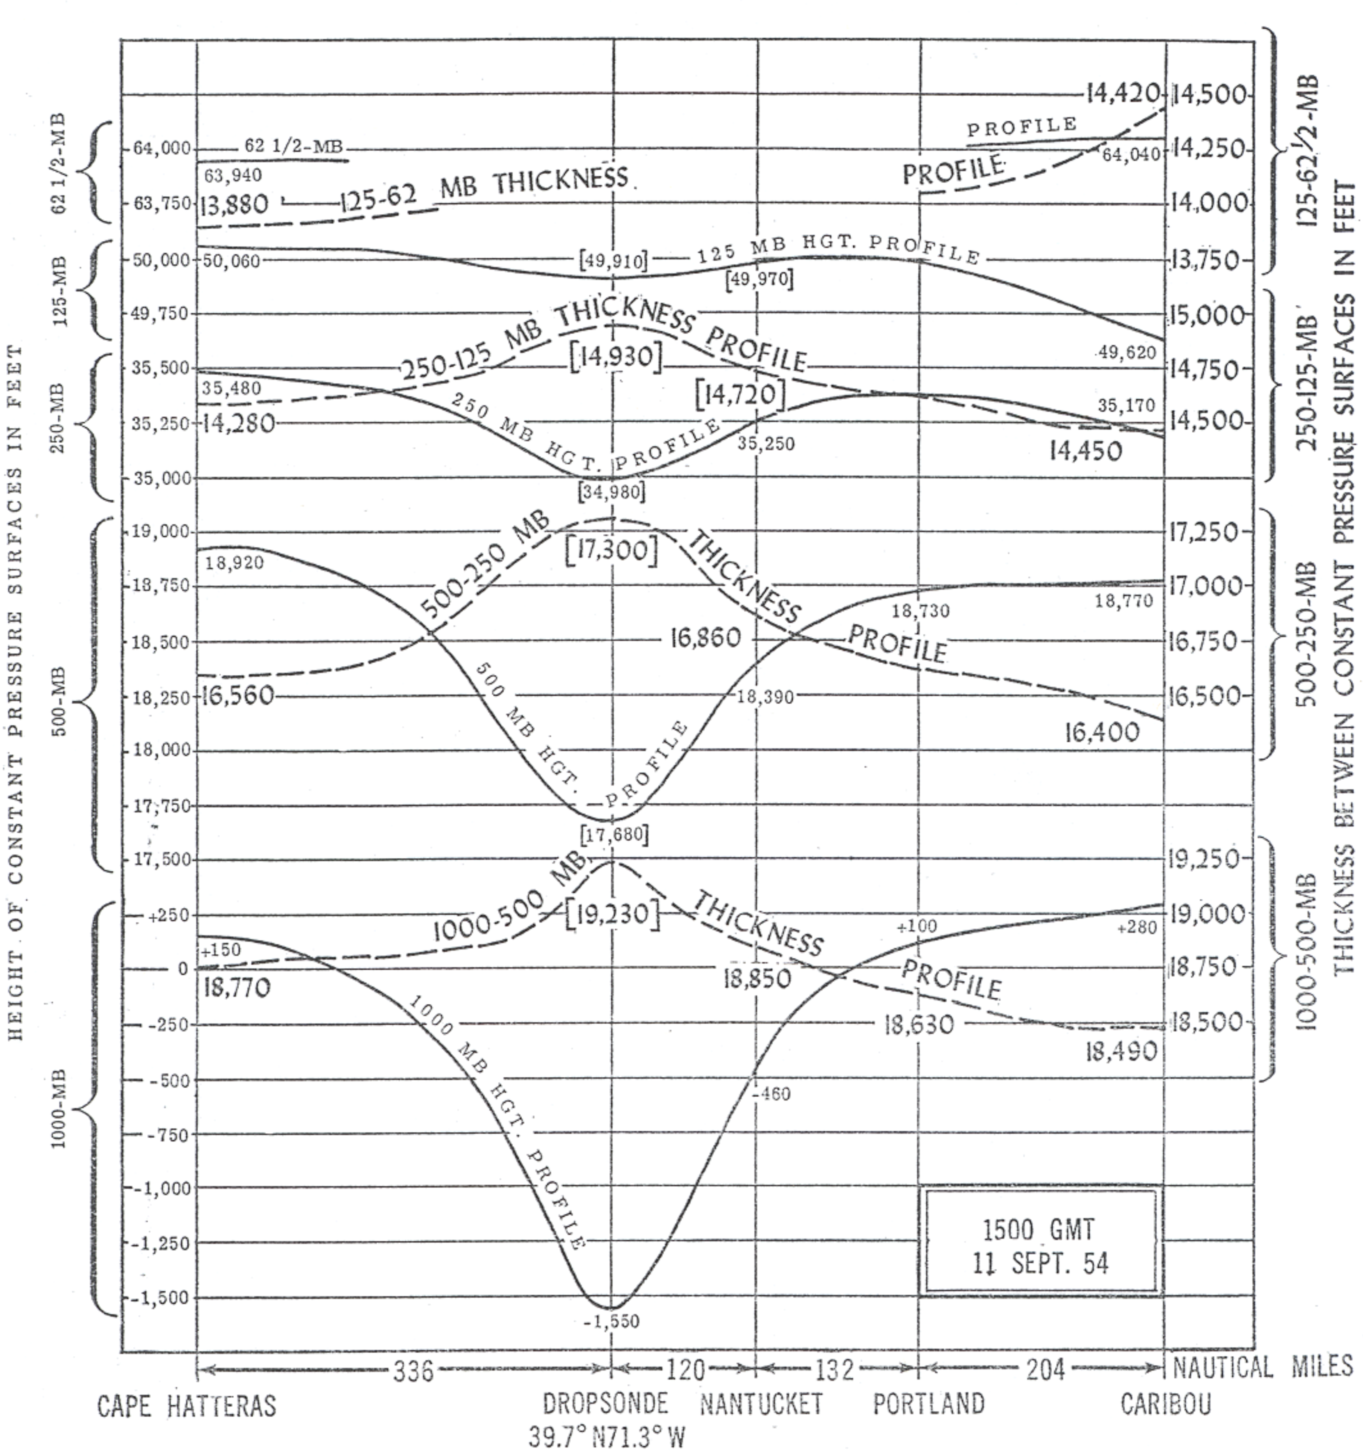

FIGURE 8.—Cross section for 1500 GMT, September 11, 1954, through the eye of Edna. The dropsonde was made in the eye. Heights of constant pressure surfaces are shown as dashed lines. Figures over stations are height and thickness values. Brackets indicate approximations.

SECONDARY DIP IN BAROGRAM

In figure 9, selected barograph traces from hurricanes Carol and Hazel have been superimposed over that of Edna. The secondary dip, not present with Edna, is a distinct and surprising feature in the traces of the other two. These secondary pressure troughs are astonishingly like the dip shown by Pierce [8] on the barograms of the New England hurricane of September 21, 1938. All traces examined indicate the duration of falling pressure to be about 15 minutes.

The explanation of the dip offered by Pierce [8] was the presence of another cyclonic circulation within the main storm. If so, this would be in contrast to the known instances of tornado type vortices embedded within hurricanes, which to this date, have only been observed in the forward semicircle of the advancing tropical storm [9]. Several meteorological conditions associated with

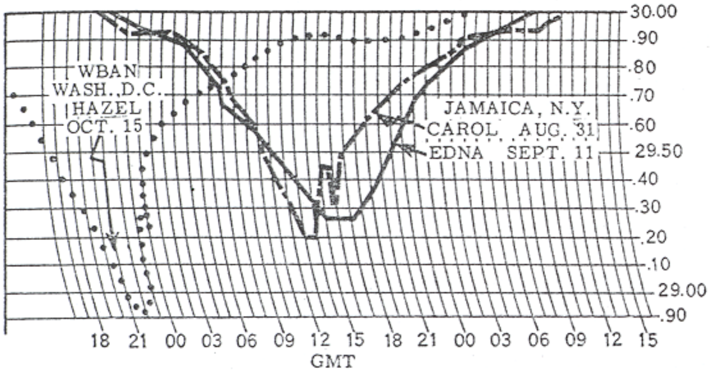

FIGURE 9.—Barograph traces showing secondary falls after passage of main center. Dates after name of hurricane denote date of lowest pressure.

Edna might reasonably have been expected to show the dip that, contrariwise, did not materialize. For example, forecasters were surprised by the strong northwest winds in eastern Massachusetts that were observed several hours after the occurrence of the lowest pressure. Furthermore, the press raised considerable comment about a double eye, and some pilots reported noting visually two cyclonic circulations over the Cape Cod area. A more complete explanation of this secondary fall of the barometer, and its possible relationship to the mechanics of a decaying hurricane, should provide an interesting subject for research.

500-MB. FLOW OVER THE STORM

Figure 10 shows the flow at 500 mb. in the neighborhood of Edna at a time shortly after recurvature, but when the center had surprisingly begun to decelerate. This situation therefore represented a difficult forecasting problem. What actually transpired, in preparing the forecast, involved among other considerations, a decision to place heavy dependence on the Petterssen wave speed equation [10] for the eastward movement of the 500-mb. trough extending through Wisconsin at 0300 GMT, September 10. This computation moved the trough axis to central Pennsylvania on 1500 GMT of the 11th, requiring southwesterly flow aloft along the Atlantic Coast at verification time. The storm was accordingly steered in a direction consistent with these developments aloft, and was forecast to pass over the Cape Cod area [11].

The forecast based on upper air information available 12 hours later, 1500 GMT, September 10 (fig. 11), was slightly less perplexing, in that the trough was advancing at a uniform speed, and the hurricane center, by 1830 GMT of the 11th, was again accelerating northward, thereby increasing the probability of Edna being "picked up" by the trough aloft.

SURFACE STREAMLINE ANALYSIS

Further interest has recently been aroused by Sherman and Carino [12] and Sherman [13] in the advantages of definitely locating singular points when performing stream-

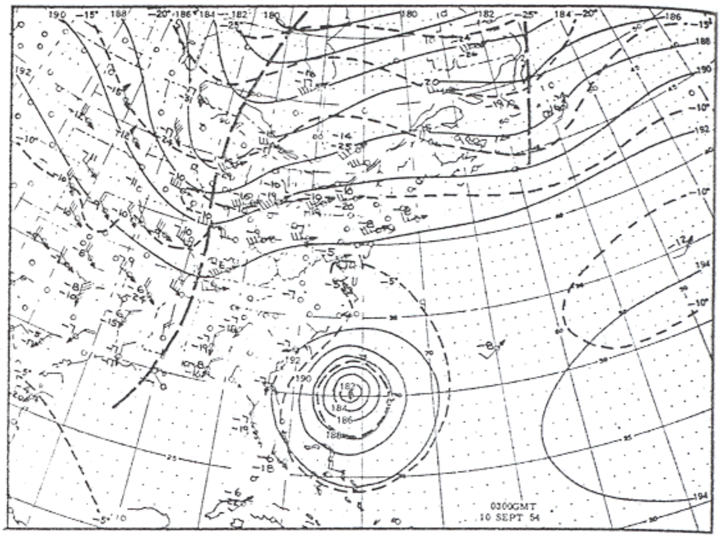

FIGURE 10.—500-mb, chart for 0300 GMT, September 10, 1954. Contours (solid lines) are in hundreds of geopotential feet. Isotherms (dashed lines) are in °C. Troughs are shown as heavy dashed lines. At this time Edna was not in the westerlies.

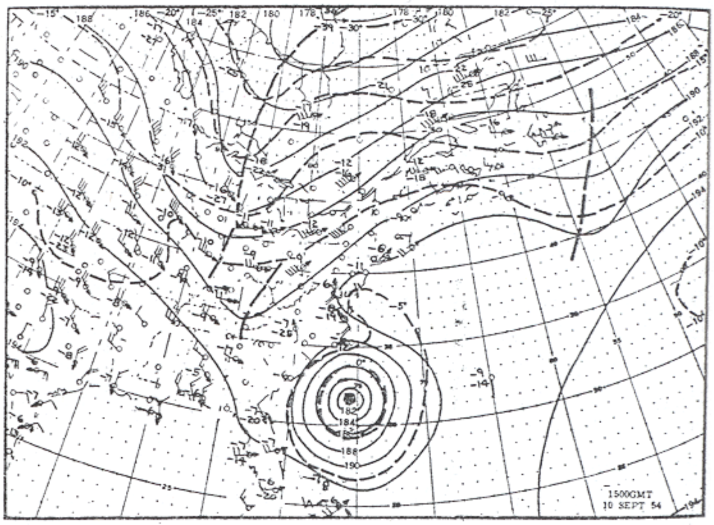

FIGURE 11.—500-mb. chart for 1500 GMT, September 10, 1954.

line analysis in the neighborhood of tropical storms. Such an analysis involves locating not only the positive, cyclonic indraft point, but also a negative, so-called hyperbolic point, where the wind direction is likewise not defined, and consequently the wind speed is zero. An example of such an analysis is shown in figure 12. Several diagrammatic views of flow and streamline analyses involving hurricanes, vividly protraying the hyperbolic point, have been prepared by Wobus [14]. The hyperbolic and cyclonic-indraft points are supposed to be related to the embedding current. One such relationship involves the orientation of the hyperbolic point from the storm center. The point is frequently located in the left forward quadrant of a tropical storm, and if rapid changes in orientation occur, recurvature may be anticipated even while more positive indications are still lacking. It may therefore be appropriate to relate briefly some of the results of such an

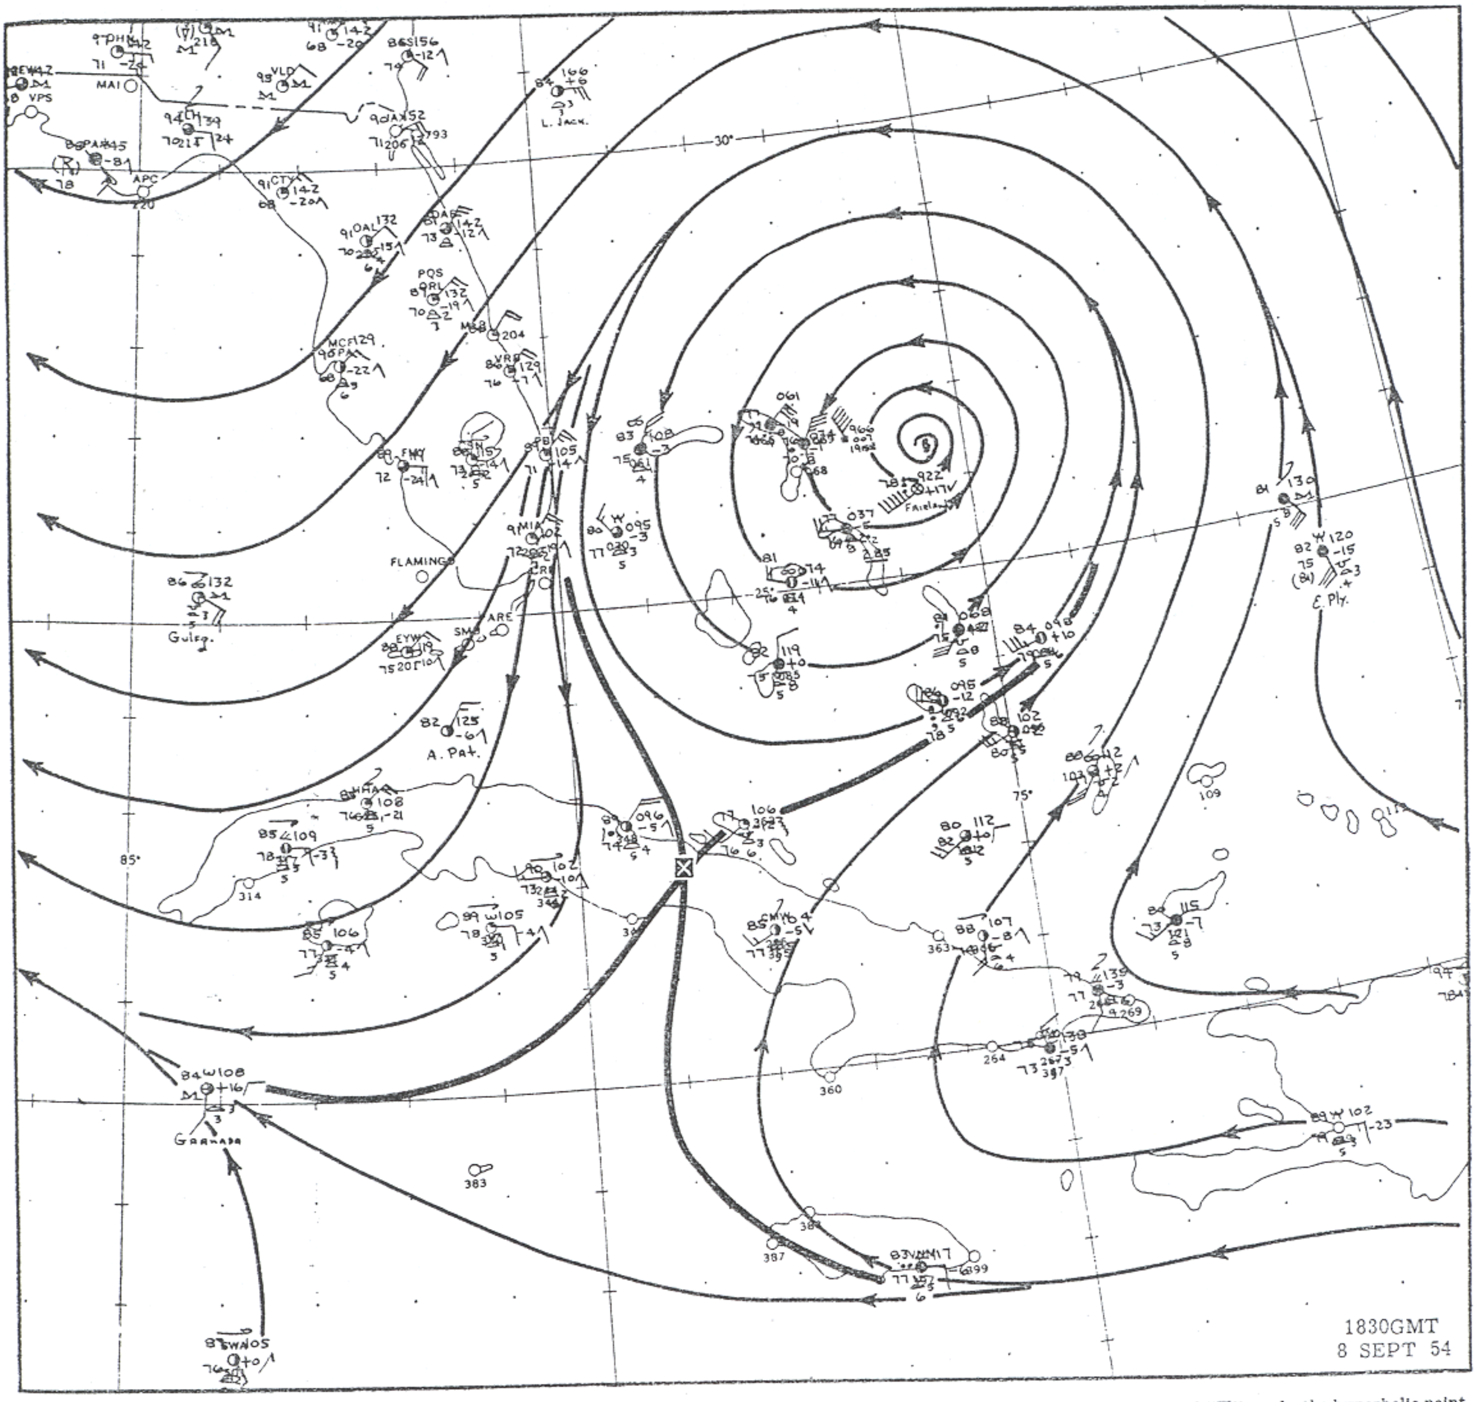

FIGURE 12.—Sample surface streamline analysis (as prepared under operational conditions). Heavy lines illustrate axes of inflow and outflow, and "X" marks the hyperbolic point. Data are from surface weather reports for 1830 GMT, September 8, 1954.

analysis of Edna for the surface level. As our interest was in the value of such an analysis from an operational standpoint under time limitations our streamlines were sketched rapidly, based on only hasty judgments concerning the reliability of questionable wind reports. The period selected for the analysis was from 0030 GMT September 6 to 0030 GMT September 10 inclusive, an interval which covered all the 6-hourly surface maps from the time of formation of Edna until just after recurvature would have been evident from the usual indications.

Following the procedure of Sherman and Carino [12], the analyses were performed by two analysts working independently. In figure 13 we have superimposed the track of the hyperbolic points obtained by one analyst over that obtained by the other, as a means of comparing the extent of agreement between them. This summary of the tracks of the hyperbolic points may be compared with a similar figure given by Sherman and Carino [12]. We have no intent of drawing any general conclusions from just this one case, of the usefulness in current synoptic practice

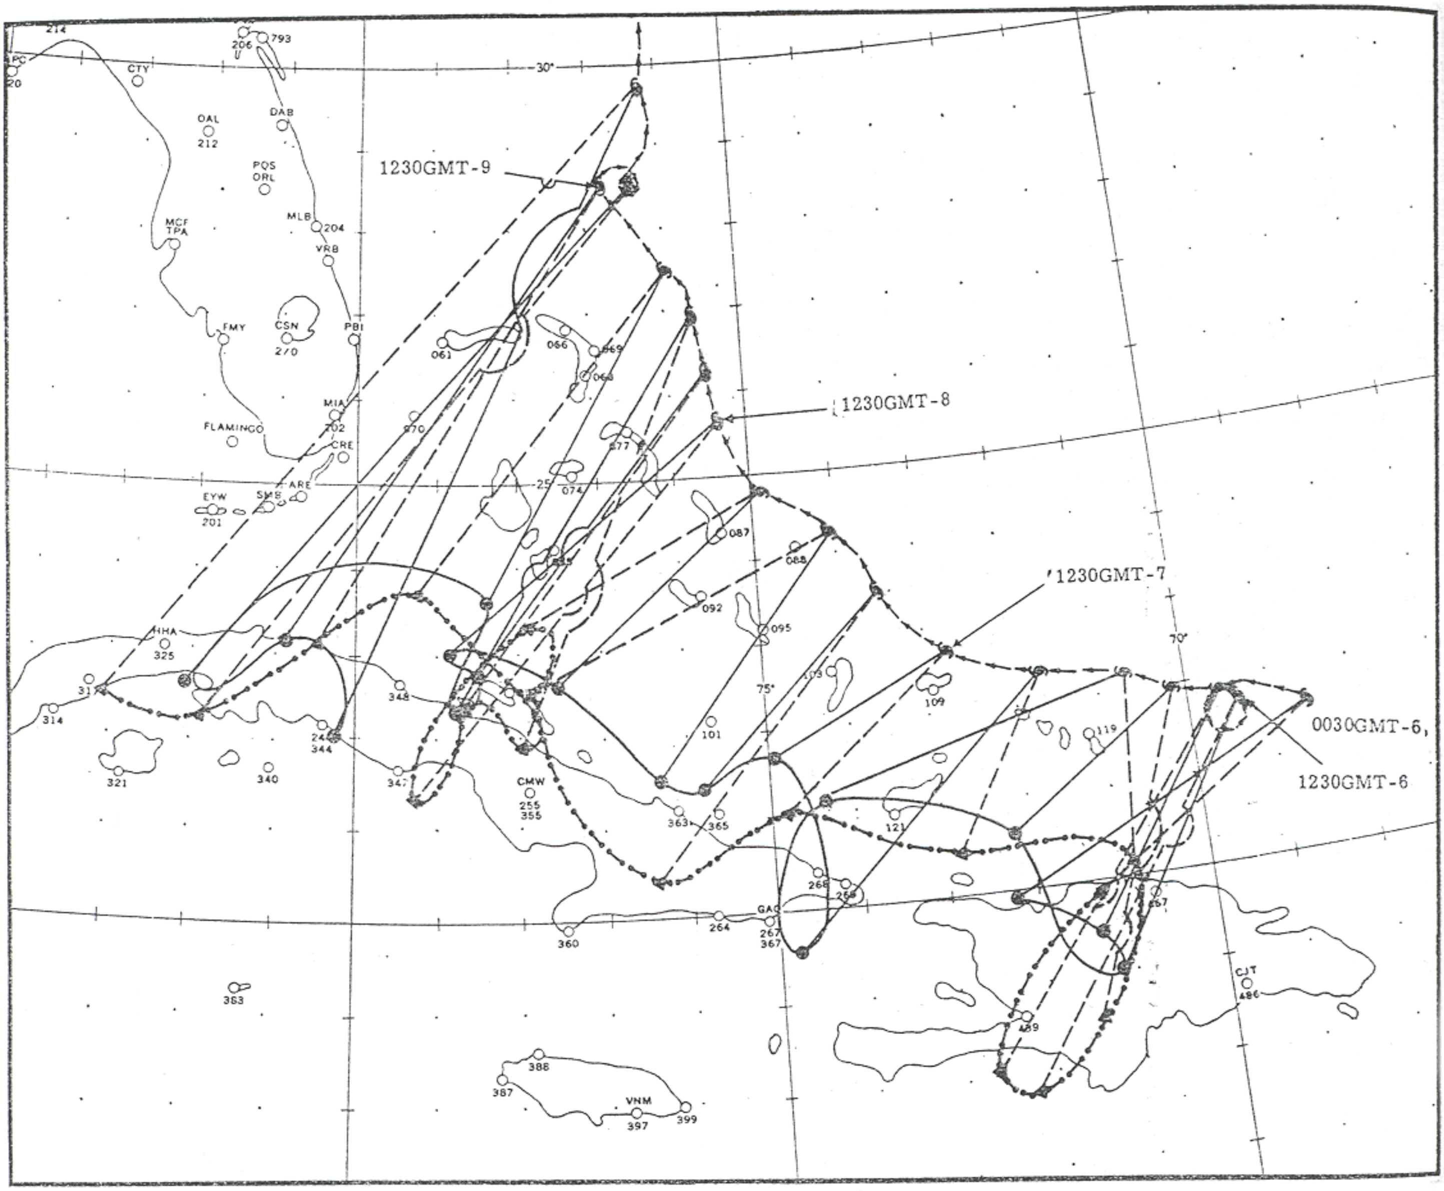

FIGURE 13.—6-hourly positions of hurricane Edna shown by conventional symbol; first analyst's position for the hyperbolic point by solid dots (track of points by solid line), second analyst's by solid triangles (track of points by dashed line).

of analyzing with special attention to the hyperbolic point. We were impressed in several instances by the inability of the analysts to reach reasonably close agreement on the location of the point, due principally, we all felt, to sparsity of data. From an after-casting standpoint, there are indications that at those times when the storm center is moving more erratically and slowly, such as when looping, the hyperbolic point fluctuates correspondingly.

STEERING ASPECTS

In attempting to forecast the movement of hurricanes, meteorologists have for many years given considerable attention and a wide range of interpretation to the rather vague concept of steering. Some interpretations of the steering principle are based on reasoning as stated by James [15] that "if a vortex is embedded in a constant wind field it will move in the direction of the general wind, and the maximum wind around it will have the same direction owing to the mutual reinforcement of the two systems." "This," James continues, "is the kinematic basis of the forecasting rule that a closed pressure system tends to move in the direction of the strongest wind about it." Because it is necessary "to identify a general circulation of dimensions large compared with those of the individual vortices, prognostications of the kinematic theory are valuable only in the case of disturbances of small dimensions such as tropical cyclones." Like many other forecasting precepts, there have been instances when steering has appeared to give erroneous results or has been difficult to apply because of data deficiencies, as for example in the case of typhoon Doris, 1950 in which different steering results were obtained by different analysts (see [16] and [17]).

Without enumerating the variety of views on the subject, the idea of some single level serving to determine *per se* the speed and direction of a hurricane has been demonstrated by Jordan [18] to be an over-simplification of the problem, and she holds that steering involves the determination of a mean wind representative of the greater part of the troposphere. Jordan showed that, on the average, tropical storms were steered by the pressure-weighted mean flow from the surface to 300 mb. and extending 4° of latitude from either side of the storm. The above relation, it must be remembered, has been shown to hold only when observations are averaged for a large number of storms. In individual instances faced by the forecaster, and in our study of Edna, a serious obstacle to computation of such a pressure-weighted flow is lack of sufficient, if any, wind reports within reasonable distances of the tropical storm at necessary times. Thus we were led to make some trial pressure-weighted wind computations using the geostrophic wind, as measured from the contour spacing on the constant pressure level analyses, at all points where wind observations were lacking. In the few instances where the contours had considerable curvature, the gradient wind was used. Usually, where data are sparse, and especially at low altitudes, one is apt to feel lack of confidence in winds estimated from such geostrophic computations. But the use of such estimates seemed to be the best currently available under operational circumstances. The analyses of all levels below 200 mb. had been made consistent by differential techniques, which offered some encouragement. Because our initial misgivings changed to some surprise at the results obtained from several of such computations, they are briefly described in the following.

The computations of pressure-weighted wind values were made at selected positions along the track of Edna corresponding to times when the future movements were most uncertain or otherwise crucial from a forecasting standpoint. The aim was to compare the pressure-weighted wind in the vicinity of the storm with the actual observed instantaneous motion of the hurricane center taken from observed positions along the track. The computations depend for the most part on geostrophic approximations that would have been available to the forecasters.

Four points at 6° of latitude from each storm center location were taken for evaluation; one point to the left and another to the right, and one to the front and another to the rear of the storm. The distance of 6° of latitude was selected because such a radius, with respect to the average size of Edna along this portion of the track, extended to just beyond the area of winds moving in an apparently closed circulation. The hurricane was assumed to be vertical at all times. The winds were determined over each point at 1,000, 850, 700, 500, 300, and 200 mb. Thus, winds from each of the constant pressure analyses regularly prepared in the WBAN Analysis Center were weighted, with the exception of those from the 150-mb. chart. Each wind was broken up into north or south and east or west components. Then, somewhat after the manner used by Jordan [18], components from the points to the left and right of the center were added vectorially, reduced by one-half, and then weighted at each respective level, and then divided by the sum of the weights. The identical process was carried out for each pair of winds to the front and rear of the hurricane, thereby obtaining what may be considered the cross-current correction to the tangential steering component. The tangential and cross-current weighted winds were added vectorially to get the resultant pressure-weighted average wind.

The weights assigned to the winds at the respective upper levels were determined by the pressure differences between top and bottom of the corresponding strata, as indicated in table 1.

Table 1.—*Wind levels and corresponding strata and weights used in computing pressure-weighted winds*

Wind level (mb.)	Stratum (mb.)	Weight
1,000	1,000–900	100
850	900–800	100
700	800–600	200
500	600–400	200
300	400–250	150
200	250–200	50

Table 2.—*Pressure-weighted winds and corresponding instantaneous velocities of Edna at the times indicated*

Time (GMT)	Date September	Velocity of center		Velocity of pressure-weighted wind	
		Direction (degrees)	Speed (knots)	Direction (degrees)	Speed (knots)
0300	6	115	10	100	08
1500	6	115	7.5	110	07
1500	9	205	5	200	07
0300	11	210	24	220	28

A comparison between instantaneous velocities of Edna, as estimated from the track, and the velocities of the corresponding pressure-weighted winds representative of the environment, is shown in table 2. The degree of agreement with respect to both direction and speed is, we feel, encouraging for further individual applications of the pressure-weighted wind technique. The results also seem to reflect credit on the consistency obtained from the differential techniques used in the preparation of the constant pressure analyses. It was noted that in the first two computations when the storm was moving essentially westward, the actual velocity of the center was slightly to the north of the direction given by the pressure-weighted wind. An interesting speculation is that this might be accounted for by what has been called the Rossby effect, by which cyclonic vortices in the Northern Hemisphere are subjected to a slight poleward acceleration due to the variation of the Coriolis parameter across the width of the storm [19].

A semi-objective technique for the prediction of tropical

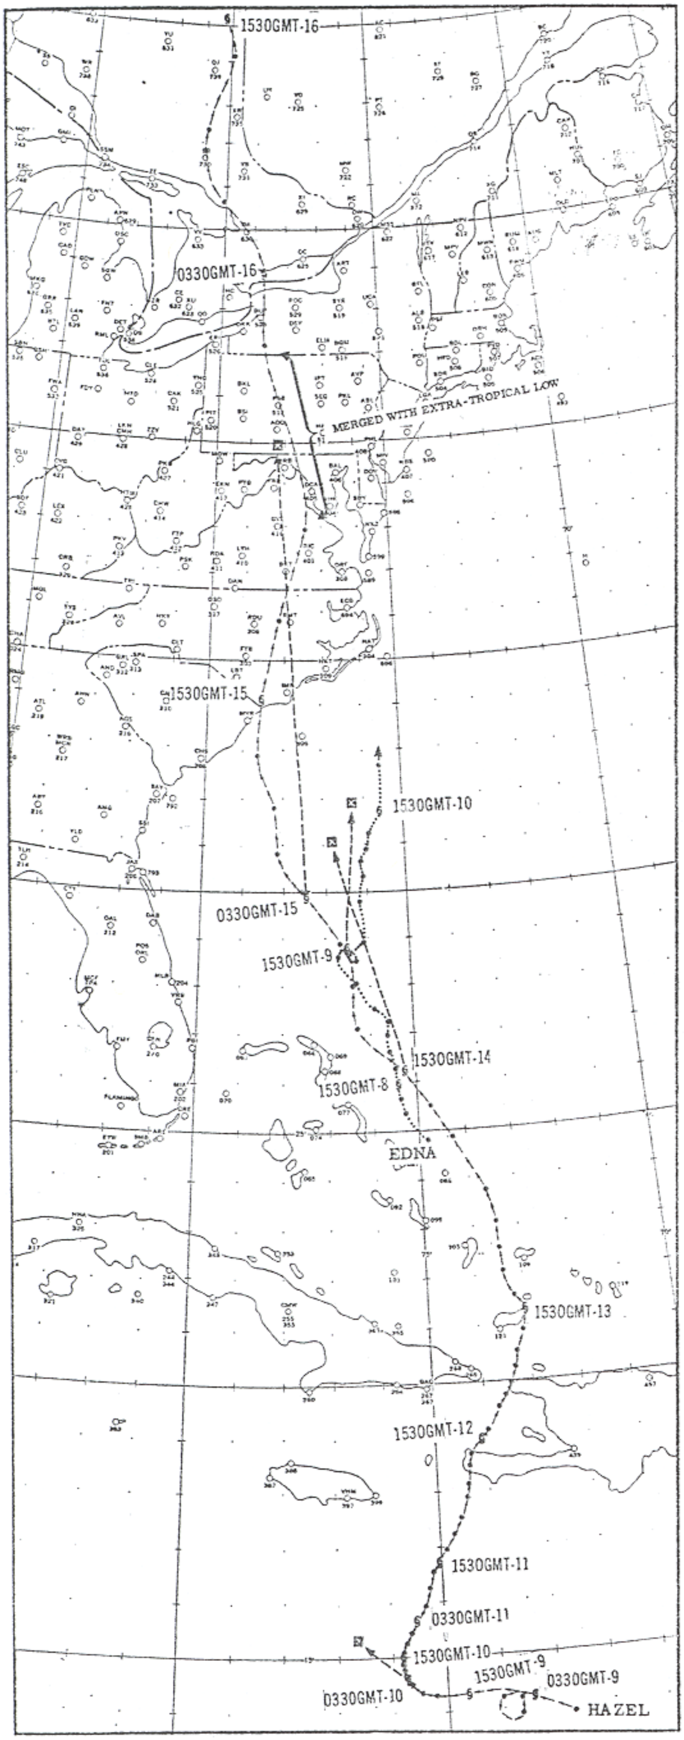

FIGURE 14.—Portions of the observed tracks of Hazel and Edna. The dashed lines ending at the "X's" denote the computed positions 24 hours from the time shown at the beginning of the dashed lines.

cyclone tracks, patterned after the methods used by George and collaborators [20], for forecasting the 24-hour displacement of extratropical storms, has been tentatively established by Riehl and Haggard [21]. While recognizing the influence of the overall tropospheric current, operational exigencies led Riehl and Haggard to search for parameters that would be approximately equivalent to the mean tropospheric flow, yet be based solely on the contour heights at 500 mb.

The Riehl-Haggard computation involves the recording and subsequent manipulation of a set of 500-mb. height values read at points determined by a somewhat variable grid over and surrounding the hurricane center. As the development of the method admittedly emulated the techniques employed by George [20], one is not surprised to find a graph and "types" entering into the calculations. This new technique, incidentally, like the method we used to compute pressure-weighted winds, is indirectly but strongly dependent on geostrophic approximations, and therefore presupposes painstakingly prepared analyses. Furthermore, in making either the pressure-weighted wind or Riehl-Haggard computations, groups of several independent readings or steps are involved, making it difficult to introduce any bias into the final result.

The Riehl-Haggard method was applied once along the track of Edna, when at upper air sounding time the center happened to be located in a critical position with respect to the forecast, and also applied three times along the track of hurricane Hazel, 1954, when the center was similarly located. Because these few trials of this new technique gave useful forecasts in situations selected for their complexity and difficulty, the results have been listed and depicted in table 3 and figure 14, respectively. At those times when the storm center is moving quite slowly, as at 0300 GMT October 10 in the case of Hazel, it is reasonable to expect the forecast system to give much better results for speed than for direction. As can be seen from figure 14, this was the case. Furthermore, the computation made at 0300 GMT on the 15th for Hazel which gave a result that was too slow, may not have been a fair trial of the method, which was not intended to predict movement "after the first day following final recurvature." Judging from these few applications further use of the technique is warranted.

TABLE 3.—*Results of Riehl-Haggard computations at several selected positions along tracks of hurricanes Edna and Hazel, 1954*

Hurricane	Date 1954	Time GMT	Location of center of storm at prog. time	24-hr. displacement of storm in degrees of latitude N–S, in degrees of longitude E–W	
				Actual	Predicted
Edna	9 Sept.	1500	28.6N, 76.5W	3° to N 1° to E	3.2° to N 0.2° to E
Hazel	10 Oct.	0300	14.6N, 75.5W	1° to N 0.2° to E	0.6° to N 0.9° to W
Hazel	14 Oct.	1500	26.4N, 75.4W	7.7° to N 3.4° to W	4.9° to N 1.6° to W
Hazel	15 Oct.	0300	30.0N, 77.7W	14° to N 1.2° to W	10.1° to N 0.6° to W

Charts of mean temperature (thickness) for the 700 to 500-mb. stratum at times shortly after recurvature, 0300 and 1500 GMT, September 10, have been prepared by Simpson [4], and the track that Edna followed does provide an additional case in support of Simpson's theory [22] of warm tongue leading and steering of tropical cyclones.

ACKNOWLEDGMENTS

John J. Smiles of the WBAN Analysis Center gave the authors invaluable assistance by preparing several of the figures, and checking many of the computations.
